18   **Abstract**

19   Advances in particle sensor design and manufacturing have enabled the development of low-

20   cost air quality monitors (LCMs). The sensors use light scattering to estimate mass concentration

21   and thus require evaluation for aerosols of varied composition and size distribution. We tested the

22   performance of six LCMs designed for home use and having a retail price under US$300 in

23   October 2018. We assessed their performance by comparing their output to reference PM$_{2.5}$ and

24   PM$_{10}$ measurements from 21 common residential sources and from infiltrated outdoor PM$_{2.5}$.

25   Reference data were obtained by using gravimetric measurements to adjust time-resolved output

26   from an aerosol spectrometer with both electrical mobility and optical particle sensors. Compared

27   by linear regression to reference measurements, LCMs had negative intercepts and slopes of 1-2

1   for infiltrated outdoor $PM_{2.5}$. Semi-quantitative responses (~50–200% of actual $PM_{2.5}$) were

2   obtained for varied aerosols including minerals (ultrasonic humidifier, vacuuming, test dust);

3   combustion products (incense, mosquito coil, extinguished candles); microwave popcorn; and

4   cooking involving frying or grilling. LCMs had low or no response to sources for which all mass

5   was in particles smaller than 0.25 μm, including steady candle flames and cooking without frying

6   or grilling. PM_{10} data from LCMs was more variable than $PM_{2.5}$.

7   **Key Words:** Combustion; Consumer IAQ monitor; Cooking; Exposure; Intervention; Source

8   control.

1. Introduction

10   Adverse health effects from fine particulate matter inhalation is a global health concern. A U.S.

11   Environmental Protection Agency[1] review concluded that increased exposure to ambient particles

12   smaller than 2.5 μm in diameter, $PM_{2.5}$, causes increased cardiovascular morbidity and mortality,

13   and likely causes increased respiratory illness. Much exposure to ambient $PM_{2.5}$ occurs in

14   residences, where we are also exposed to particles emitted by activities including smoking,

15   cooking, burning incense and candles, crafts, and settled dust re-suspension. Indoor air quality

16   (IAQ) monitoring can provide feedback on efforts to protect occupants from infiltrating (high)

17   outdoor $PM_{2.5}$, help to identify indoor activities that generate PM[2, 3], or automatically activate

18   ventilation or filtration when readings exceed a designated threshold[4]. The potential to incorporate

19   IAQ monitoring into smart home management systems is receiving increasing attention[5, 6].

20   A common standard for $PM_{2.5}$ measurement is the U.S. EPA's gravimetric Federal Reference

21   Method[7, 8] (FRM). The time resolution of filter-based sampling is constrained by the need to collect

22   enough particles to reliably discern a change in filter mass and the high cost of weighing and

23   handling filters. To enable higher time resolution regulatory monitoring, the US EPA offers a

24   Federal Equivalent Method (FEM) designation that is obtained by demonstrating correlation to an

25   FRM when sampling ambient aerosols[8]. FEM monitors offer hourly or better resolution.

1   Even higher time resolution (minute scale or better) is achieved by devices that estimate particle

2   concentrations based on light scattering, utilizing either photometry or optical particle counting.

3   In photometry, the scattered light from an ensemble of particles passing through the sensor cell is

4   translated to mass concentration based on a reference calibration[9, 10]. Since photometers require

5   calibration to the specific aerosol of interest, some professional grade models include onboard

6   filter sampling. Optical particle counters (OPCs) use assumptions about particle shape and

7   refractive index to calculate the size of each individual particle that scatters laser light while

8   passing through the sensor cell. Particles are assigned to size bins and mass concentrations are

9   estimated using assumptions about density or through calibration to reference measurements[9].

10   Many published studies on time-resolved $PM_{2.5}$ in occupied homes have used photometers or

11   optical particle counters[11-19]. Several studies have reported large variations in the calibration or

12   response factors for professional grade optical monitors measuring aerosols relevant to residential

13   $PM_{2.5}$, and variations of 30–50% over time for some sources.[13, 20-22]

14   Real-time monitoring of fine particles within homes is now possible with devices that utilize

15   mass produced optical sensors and cost under US$300. Low-cost monitors (LCM), described

16   elsewhere as "consumer grade"[22, 23], vary in their reporting interface (e.g., on device or via cell

17   phone), time-resolution of data reporting, and their ability to communicate with control equipment

18   using smart home platforms. Particle levels may be reported in mass concentration units ($\mu g\ m^{-3}$),

19   as particle number concentrations, as an air quality index (AQI) or as a score on a proprietary scale.

20   There is a rapidly growing literature on the performance of low-cost sensors and monitors for

21   ambient particles[24], but fewer studies focusing on IAQ. In ambient studies, sensors are compared

22   against regulatory monitoring equipment over weeks to months[25-37], and some have proposed

23   sophisticated algorithms to account for humidity and other environmental factors[38]. The most

24   extensive and systematic evaluations have been done by the South Coast Air Quality Management

25   District's Air Quality Sensor Performance Evaluation Center (AQ-SPEC) (www.aqmd.org/aq-

26   spec) using methods described in a recent paper[39]. The US EPA also provides resources via their

27   sensor toolbox website (www.epa.gov/air-sensor-toolbox).

1   For aerosols relevant to residential exposures, Dacunto et al.[40] reported calibration factors to

2   relate output of the Dylos DC1100 monitor to gravimetric measurements for 17 common

3   residential particle sources. Manikonda et al.[41] evaluated several monitors (AirAssure, AB

4   AirSense, Dylos, Speck) measuring cigarette smoke and Arizona Test Dust in a room-sized

5   chamber. Singer and Delp reported response factors for seven monitors (AirBeam, Air Quality

6   Egg, AirVisual Node, Awair, Foobot, Purple Air PA-II, Speck) measuring various residential

7   sources in a lab[22]. Zou et al. compared output of 3 bare sensors and 5 devices (not identified) to

8   reference measurements for 27 emission events in a house[42]. Curto studied two monitors (HAPEX

9   Nano and TZOA) measuring wood smoke leakage from fireplaces in U.S. homes and cooking in

10 Indian homes[43]. Zamora et al. evaluated the Plantower PMS A003 with cooking emissions in a

11 small apartment[37]. Wang et al.[44] and Sousan et al.[45] systematically studied the performance of low-

12 cost sensors measuring particles of varying sizes and compositions in controlled laboratory testing.

13 The objective of this study was to evaluate the performance of LCMs (of 2018 vintage) for

14 measuring common residential sources of fine particles. The approach largely follows a 2017

15 study[22] that reported semiquantitative (within 2x actual) responses of four monitors to most of the

16 sources tested, very low or inconsistent responses of 3 monitors, and an inability of all the monitors

17 to detect emission events that were comprised entirely of particles with optical diameters of <0.3

18 μm. Specific drivers of the current study were the availability of updated versions of three monitors

19 (Awair2, Air Quality Egg 2018, and AirVisual Pro) tested previously, an indoor version of the

20 Purple Air (PAI), and two monitors not previously evaluated (Kaiterra Laser Egg 2 and Ikair).

21 **2. Method**

22 **2.1. Low-cost monitor selection**

23 Candidate monitors were identified from recent review papers[46, 47] and by searching internet

24 marketplaces for combinations of the terms (meter or monitor) and (indoor air quality, air

25 quality, dust, particle, or PM). Monitors selected for testing met these criteria: (1) has sensor for

26 $PM_{2.5}$, "fine particulate matter" or "fine particles"; (2) reported particle mass concentrations, not

1   only AQI; (3) has internal data logging or accessible cloud storage at 5-min or better resolution;

2   (4) displays real-time data on device or mobile app; and (5) available for retail purchase in the

3   U.S. or China in October 2018 at cost of US$300 or less. Any device previously determined to

4   have inconsistent correlation to reference monitors in published third party testing was excluded

5   unless it had been updated to address the performance issue. The six monitors shown in Table 1

6   were selected and purchased.

7   **2.2. Reference measurements**

8   Reference measurements were obtained using a Tapered Element Oscillating Microbalance

9   (TEOM) with Filter Dynamic Measurement System (FDMS) (Model 1405-DF, Thermo Fisher

10   Scientific), and by collecting filter samples for gravimetric analysis. The FDMS version of the

11   TEOM is an FEM that intermittently (a) collects sample onto a microbalance filter for mass

12   concentration determination, then (b) draws filtered air over the microbalance filter to quantify any

13   gain or loss from semivolatile compounds. The configuration and processing of TEOM output to

14   obtain 6-min resolved data is described in the Supplementary Material (SM). Gravimetric samples

15   were collected using 37 mm diameter, 2 μm pore-size, TEFLO (Pall) PTFE filters and two

16   AirCon2 High Volume Air Samplers (Sensidyne) at target flow rates of 10.0 lpm. The flow was

17   checked before each sample using a Gilian Gilibrator2 (Sensidyne). Size selection was

18   accomplished using MSP Model 200 Personal Environmental Monitors (PEM-10-2.5 and PEM-

19   10-10) for $PM_{2.5}$ and PM_{10}, respectively. Filter samples were started just before the emission event

20   and collected at least through the end of the source-generating activity and often until particle

21   concentrations were close to pre-source levels (Table S1). Filters were equilibrated at a

22   temperature of 19.5 ± 0.5°C and relative humidity of 47.5 ± 1.5% for at least 24 hours before

23   weighing pre-and post-sampling on a Sartorius SE2-F ultra-microbalance.

24   A Grimm Mini Wide-Range Aerosol Spectrometer Model 1371 (WRAS) was used as a

25   reference transfer for one minute resolved data and also to provide distributions of particle number

26   and mass concentrations. The WRAS combines an electrical mobility analyzer that counts particles

27   in 10 size bins from 10 to 193 nm with a laser-based optical particle counter that provides counts

1   in 15 bins from 0.25 to 2.5 μm and 16 bins from 2.5 to 35 μm. WRAS output was adjusted with

2   source-specific factors determined using the filters and TEOM, as described in Section 2.7.

3   **2.3. Professional grade particle monitors**

4   Measurements were additionally made with two professional grade aerosol photometers: a

5   Met One Instruments BT-645 (BT) and a Thermo pDR-1500 (PDR). These instruments have

6   wide measurement ranges, from 1 μg m^{-3} to 100 and 400 mg m^{-3}, respectively. They use lasers

7   with wavelengths of 670 and 880 nm, respectively, and have active flow control and filtered

8   sheath air to keep their optical paths clean. The PDR features temperature and humidity

9   compensation. The BT is calibrated with 0.54 μm polystyrene latex spheres and the PDR is

10 calibrated with Arizona test dust (ISO 12103-1, A2 Fine). Manuals for both recommend that the

11 instruments should be adjusted for specific sources or sampling environments by co-located

12 gravimetric sampling. The PDR has an onboard filter slot.

13 **2.4. Test room set up**

14   All experiments occurred in a single-story 120 m^3 laboratory room with three external walls,

15 two doors and raised ceiling. Particle monitors were placed on or adjacent to a wire shelving unit

16 in the central area, several meters from source activities (Figure 1). Outdoor air was supplied to

17 the chamber through a HEPA box air filter (McMaster-Carr 2153K49) at an air exchange rate of

18 1.4–1.5 h^{-1}. The rate was measured several times through the testing period by tracer decay. Small

19 fans were operated to mix the air.

20 **2.5. Source descriptions**

21   Table 2 presents brief descriptions of the 24 source experiments. Several sources were used in

22 multiple experiments, sometimes with variations. Sources are discussed in the following groups.

23 Mineral sources included an ultrasonic humidifier with the filter removed, Arizona Test Dust, and

24 vacuuming with the HEPA filter removed. Recreational combustion included candles burning and

25 being extinguished (with separate filters collected for each phase), stick incense and mosquito

26 coils. Electric cooking activities included microwaving popcorn, cooking of beef burgers on an

27 electric grill (e-grilling), heating oil in a steel wok on an induction stove, and toasting 6 slices of

1   bread in a toaster. There were four cooking activities with pan-frying (bacon, eggs, fish) or stir-

2   frying (spinach), all on gas burners. And there were four cooking experiments that did not involve

3   frying or stir-frying: boiling potatoes on a gas stovetop and separately broiling Brussel sprouts,

4   potatoes, and bacon in a gas oven.

5   To evaluate the performance of the low-cost devices at measuring indoor concentrations of

6   infiltrated outdoor $PM_{2.5}$, data were also collected during two overnight periods during which the

7   filtered ventilation air was turned off and the exterior door was partially opened to increase outdoor

8   air exchange. We also analyzed data from overnight and weekend periods when the room was

9   closed and the filtering of supply air resulted in very clean conditions; these data enable assessment

10 of low-cost monitor response when $PM_{2.5}$ is close to zero.

11 **2.6. Data recording and processing**

12   For the AQE and AVP, we used on-board storage and downloaded data via computer-based

13 software (AQE) or by connecting to the device via local Wi-Fi using the SAMBA protocol (AVP).

14 Data from the AW2 devices were provided by the company in response to an email request to the

15 product technical support center. Data from the LE2, PAI and IKA were obtained from online data

16 storage platforms. The LCMs and TEOM synchronized their internal clocks to official time by

17 internet connection. The WRAS clock was reset each day to the same computer, which was also

18 synchronized to official time.

19 **2.7. Data analysis**

20   The general approach to estimating the true $PM_{2.5}$ time series during source activities was to

21 use the gravimetric samples and the TEOM data to adjust the WRAS. Source-specific adjustments

22 were determined by comparing average concentrations reported by the WRAS, TEOM and filters

23 over the filter sampling intervals. Low-cost monitors were then compared to the adjusted WRAS

24 for temporal correlation (at 5-min resolution) and for accuracy measuring event-integrated mass

25 concentrations. The accuracy of LCMs for infiltrating outdoor PM and their readings when

26 exposed to clean air (near-zero values) was evaluated by direct comparison to hourly TEOM data.

1   We screened for any filter-based data that appeared to be inconsistent with the co-located mass-

2   based measurements (i.e. the other filter and TEOM). Filter-based $PM_{2.5}$ measurements were first

3   compared to TEOM data collected over the same intervals. The two were highly correlated with

4   r^2=0.94 and the filters higher than the TEOM by about 16% as a group (Figure S1 of the SM).

5   None of the paired filter and TEOM $PM_{2.5}$ measurements differed by more than a factor of 2. The

6   largest differences were for snuffed candles (0.51), dust (0.61), humidifier 1 (0.65) and boiled

7   potatoes (1.46). The error for the potatoes is assumed to be related to the small mass collected on

8   the filters (~5 mg).

9   We also compared $PM_{2.5}$ and PM_{10} filters. Since the WRAS robustly detects the particles that

10   comprise the difference, we used the ratio of $PM_{2.5}$ to PM_{10} reported by the WRAS as an estimate

11   of what the ratio should be. There were three events for which the ratio of $PM_{2.5}$ to PM_{10}

12   determined by filter samples was more than a factor of 2 different than the ratio reported by the

13   WRAS. Two of the events (on the same day, 14-Dec) appeared to have erroneous filter

14   measurements. The PM_{10} filter for the second mosquito coil experiment indicated 262 $\mu g \ m^{-3}$

15   whereas the $PM_{2.5}$ filter and TEOM had concentrations of 66.8 and 70.8 $\mu g \ m^{-3}$. Additionally, the

16   WRAS indicated that $PM_{2.5}$ and PM_{10} should have been almost the same for the mosquito coil and

17   the $PM_{2.5}$ and PM_{10} from filters were very close for the first coil experiment. For the Test Dust,

18   the PM_{10} filter indicated a concentration of 74 $\mu g \ m^{-3}$ while the $PM_{2.5}$ filter indicated 45 $\mu g \ m^{-3}$.

19   Since the $PM_{2.5}$ filter sample translated to an aerosol density of 2.34 $\mu g \ m^{-3}$, which is close to the

20   Test Dust density of 2.65 $\mu g \ m^{-3}$, we used the density adjustment factor from the $PM_{2.5}$ filter for

21   both samples.

22   As a second data check we compared $PM_{2.5}$ and PM_{10} concentrations estimated from filters for

23   all sources that the WRAS indicated had more than 95% of the PM_{10} mass under $PM_{2.5}$. If we

24   include the filters collected during the period when the room was opened to the outdoors to

25   measure ambient air overnight on 12/20-12/21 there were 14 events that fit this criterion. We

26   calculated the ratio of $PM_{2.5}$ to PM_{10} based on WRAS and also based on the filter samples. The

27   WRAS ratio for this group was 0.974+/-0.016. The ratio of gravimetric samples was 0.912±0.089.

1   This suggests a possible systematic bias of roughly 6-7% between the pumps and PEMs used to

2   sample $PM_{2.5}$ and PM_{10}. The relative standard deviation of four filter samples from the humidifier

3   experiment (which had true duplicates for both $PM_{2.5}$ and PM_{10}) was 14%. The relative deviations

4   for the other 13 pairs of $PM_{2.5}$ and PM_{10} samples had a mean of 0.118 and SD of 0.057. In all

5   subsequent analyses, we used the average of the $PM_{2.5}$ and PM_{10} gravimetric concentrations for

6   these 14 events.

7   The best estimates of actual $PM_{2.5}$ concentrations developed from the analysis described above

8   were used to adjust the WRAS data for each source. These factors are presented as density

9   adjustment factors (DAF) in Table 1. WRAS data were multiplied by DAF/1.68 as 1.68 is the

10   default density assumed in the WRAS.

11   Low-cost monitor data were visually reviewed to screen for any clearly questionable data. This

12   simple quality assurance check found that one of the AQE units occasionally reported elevated

13   concentrations when there were no sources indicated by the other two (see Figure S2).

14   **2.8. Temporal correlations**

15   To assess temporal correlation for emission events, we compared data pairs of $PM_{2.5}$ reported

16   by each low-cost monitor and the adjusted WRAS concentrations averaged over the same 5 min

17   intervals. An event analysis interval was set for each experiment by visually inspecting the time

18   series data to ensure that the entire period of elevated concentration was included (from just before

19   the start of an event until after the room has decayed to pre-event levels). Low-cost monitor data

20   were regressed against the adjusted WRAS for each source using a linear model with zero

21   intercept, a linear model with floating intercept, and a second order polynomial with floating

22   intercept, and the R^2 was calculated for each fit.

23   **2.9. Calculation of time-integrated concentration by source event**

24   Performance for measuring events was assessed as a monitor's ability to accurately report the

25   time-integrated concentration over the event. Events were quantified by subtracting the baseline

26   room air concentration before and after the event. For each device, the baseline was identified by

27   first masking all data points >2 μg m^{-3} above the concentrations measured at the start and end of

1   the interval. This baseline was then subtracted from each data point in the interval and baseline-

2   subtracted concentrations were integrated over time. Ratios of device response to adjusted WRAS

3   (estimated true PM) were calculated for both baseline-subtracted and as-reported data series.

4   **3. Results**

5   **3.1. Low-cost monitor response for clean air and infiltrated outdoor PM$_{2.5}$**

6   A common starting point for assessing instrument performance is to check the output when

7   the target analyte is absent, i.e. to check the zero. Since this study sought to assess performance

8   for realistic challenges, we conducted a near-zero check while there were no sources inside the

9   room and the supply air was effectively filtered. The hourly PM$_{2.5}$ concentrations measured by

10   the TEOM during these periods, show in Figure 2 and Figure S5 had a mean ± standard deviation

11   (SD) of 1.45±2.0 µg m^{-3}. This SD matches the manufacturer specified precision of ±2 µg m^{-3} for

12   hourly data. At these conditions all low-cost monitors frequently or mostly reported hourly PM$_{2.5}$

13   under 0.5 µg m^{-3} and several (AVP, IKA, AQE, LE2) commonly reported PM$_{2.5}$ under 0.1 µg m^{-3}

14   (Figure S5). These results indicate a small negative offset for the low-cost monitors,

15   corresponding to under reporting at very low concentrations.

16   Figure 2 also presents the hourly PM$_{2.5}$ measurements from LCMs and the TEOM during the

17   overnight periods with the exterior door slightly open to increase outdoor air infiltration and the

18   filtered supply turned off. Hourly PM$_{2.5}$ as measured by the TEOM was very low during the first

19   night and reached approximately 15 µg m^{-3} during the second night. The LCMs tracked the

20   TEOM with linear-fit R^2 values of 0.75–0.80. The variance resulted primarily from the LCMs but

21   imprecision in the hourly TEOM was also a factor at these low levels. The best fit lines had

22   negative offsets of 2-5 µg m^{-3} (Table S2), again indicating under-reporting near zero. Figure 2

23   also show that for infiltrated outdoor PM$_{2.5}$, devices with Plantower sensors (AQE, LE2, and PAI

24   in bottom row) had higher slopes than devices using other sensors (Table S2). Comparisons of

25   the TEOM to the unadjusted WRAS and the professional PM monitors are provided in Figure

26   S6. Similar to the low-cost monitors, both professional grade devices had negative offsets around

1 3 µg m^{-3} and slopes of 1.4 and 2.0. The unadjusted WRAS was much closer to the TEOM with a

2 slope of 1.2 and a positive intercept of 0.3 µg m^{-3}.

3 **3.2. Temporal correlations to estimated true PM$_{2.5}$**

4   Correlations between 5-minute average PM$_{2.5}$ reported by LCMs or professional photometers

5 and the coincident adjusted WRAS (reference) measurements are presented for all of the PM

6 sources in Figures S7-S18 of the Supplementary Material. Example LCM results for 8 sources

7 are provided in Figures 3–4. At the top of each column is the mass distribution by particle size,

8 obtained by applying the density adjustment factors in Table 2 uniformly across the size

9 distribution reported by the WRAS. As a visual aid, the PM$_{2.5}$ contributed by particles in the

10 optical range of the WRAS (starting at 0.25 µm optical diameter) are colored green and smaller

11 particles – which should be invisible to the optical sensors of the LCMs – are displayed in red.

12 Yellow shading is used to indicate mass contributed by coarse particles, between 2.5 and 10 µm

13 diameter. For most of the LCMs, there are three points at each time step, one for each unit tested.

14 The AQE that intermittently reported spurious readings was removed leaving only two units for

15 that device. Variance across units of a device is visible as vertical separation of data points.

16 Asterisks indicate measurements when concentrations were rising and open circles show decays.

17 Parameters of linear or second order fits are shown.

18   All monitors had substantial responses to the three mineral sources, as shown in Figures S7–S8

19 and the first two columns of Figure 4, with generally higher response to the unfiltered ultrasonic

20 humidifier aerosol than for the unfiltered vacuuming or Test Dust. This corresponds to the

21 humidifier having a much larger fraction of mass in the optical sensing range for PM$_{2.5}$. The AVP

22 and AW2 had the most consistent response across the three sources, providing among the highest

23 responses for vacuuming and dust, but somewhat lower responses compared to other monitors for

24 the humidifier aerosol. For these three sources, the largest variation in responses across devices

25 occurred for the Test Dust, for which the PM$_{2.5}$ mass was almost entirely at the upper end of the

26 size range. Low-cost monitor responses were highly correlated to the reference with R^2≥0.83 in all

1   cases. Similar to LCM responses, professional monitor slopes were higher for the humidifier (0.8–

2   1.2) than for the vacuum and Test Dust (0.4–0.5) (Figure S8).

3   Figures S9–S10 presents results for replicate experiments with incense and mosquito coil.

4   These sources had similar mass distributions by size, roughly split between particles above and

5   below the threshold for optical detection. Each monitor had similar responses for the two sources

6   and consistent responses for replicates. All showed high linear correlation with $R^2 \geq 0.98$. Slopes

7   were substantially above unity, indicating over-reporting of $PM_{2.5}$.

8   LCM responses to unscented candle burning and snuff phases are shown in Figure 4 and results

9   for both candle experiments are provided in Figures S11-S12. During the burn phase for unscented

10 candles, the WRAS indicated very little mass in the nominally visible range of the optical sensors,

11 yet both the LCMs and professional monitors tracked the adjusted WRAS with high linear

12 correlations ($R^2 \geq 0.95$). Slopes varied from 0.25 for the AVP to 0.76 and 0.78 for the PAI and

13 AQE, suggesting that sensors may be variably weighting the signal from the smallest particles that

14 they can detect. After the unscented candles were snuffed, mass concentrations increased and a

15 larger fraction was in the detectable range of the optical sensors; consequently, concentrations

16 reported by the LCMs were closer to the estimated true $PM_{2.5}$ (slopes closer to 1). Correlations

17 were a bit lower for this phase of the experiment owing to somewhat different responses during

18 the very short period of increasing concentrations (asterisks). During steady burning of the scented

19 candles, the adjusted WRAS indicated concentrations rising to about 25 μg m^{-3} but no LCM

20 response, as all of the mass presented in particles smaller than 0.2 μm. After the scented candles

21 were snuffed, many larger particles were formed and the mass concentrations in the $PM_{2.5}$ and

22 coarse (PM_{10}–$PM_{2.5}$) ranges were of similar magnitude to the mass concentration of particles

23 below 0.25 μm. Most of the LCMs again had initially low response (indicated by the asterisk data

24 points shown below the main correlation lines in Figure S11) and higher responses during the

25 decay. Figure S12 shows that the professional monitors had similar responses to the LCMs for

26 candles; they reported no substantial $PM_{2.5}$ during the scented candle burning phase and reported

1    $PM_{2.5}$ that was half or less of the estimated true value during the continuous burn of the unscented

2   candles. Professional monitors also under-reported $PM_{2.5}$ after candles were extinguished.

3   Results from the electric grilling of a burger and heating olive oil on an induction stove are

4   presented in Figure 4 and full results for the electric cooking group are provided in Figure S13–

5   S14. All of the monitors had high correlations to the adjusted WRAS for all of the electric cooking

6   events, though the response factors varied. The toast produced the lowest response and the olive

7   oil had the highest for most monitors. Slopes were also high for e-grilled beef burgers, which had

8   substantial mass in particles >0.25 μm. The very high response factors for the induction-heated

9   olive oil were somewhat surprising since only a small faction of its mass was in the particle size

10   range thought to be visible by the optical sensors. These results sharpen the question of how the

11   sensors are estimating mass for the smallest detected particles. Similar to the LCMs, the

12   professional monitors were highly correlated for all sources but with varying slopes (Figure S13).

13   The third column of Figure 4 presents broiled bacon as an example of cooking with gas burners

14   without frying, and results from other sources in this group are presented in Figures S15–S16. For

15   these sources, $PM_{2.5}$ was comprised entirely or almost entirely of particles smaller than 0.25 μm

16   and based on the data, invisible to the optical sensors of both the low-cost and professional

17   monitors. None of the monitors reported any significant mass despite the adjusted WRAS reporting

18   5-min average concentrations exceeding 30, 50, 100, and 100 μg m^{-3} for the four events.

19   Figures S17–S18 presents results for the four events with cooking involving frying or stir-frying

20   and the frying of bacon is shown as an example in Figure 4. For these sources, roughly half or

21   more of the $PM_{2.5}$ was in the optical detection range of the WRAS. All of the LCMs and

22   professional monitors were highly correlated to the adjusted WRAS for all four sources, with

23   slopes varying from approximately 0.5 to 1.5. For these sources, the responses across LCMs for

24   each source varied less than for any of the other source groups. We note, however, that each LCM

25   had different response to the specific frying or stir-frying sources. It is also notable that several of

26   the LCMs had a non-linear response at the very high $PM_{2.5}$ produced by the bacon frying; these

27   were fit with a second order polynomial as shown in Figure 4.

1   The correlation analysis revealed the following points. When there was substantial mass in

2   particles above 0.25 μm, all LCM $PM_{2.5}$ concentrations were linearly correlated with the estimated

3   true $PM_{2.5,}$ at least up to 200 μg m^{-3}; and slopes were almost always in the range of 0.5–2.0. When

4   the $PM_{2.5}$ was entirely comprised of particles smaller than 0.25 μm optical diameter, invisible to

5   the optical sensors of both the low-cost and professional monitors, none reported significant

6   events. Relatively high LCM responses for sources with little mass in the optically invisible range

7   raise questions about how the sensors weight the signal from the smallest particles.

8   **3.3. Accuracy for quantifying event-integrated $PM_{2.5}$**

9   In the following sections, we compare as-measured and baseline-subtracted, event-integrated

10   concentrations reported by LCMs to those from adjusted WRAS data. We used the adjusted WRAS

11   as the reference because it provided data resolved to 1 minute with no apparent delay. Figure 5

12   and Figure 6 present results as ratios of the event-integrated values for the 24 sources described in

13   Table 2. Open circles show ratios calculated using baseline-subtracted concentrations, x-symbols

14   indicate the as-measured ratios. Error bars indicate the standard deviations of the ratios developed

15   from the 2–3 units of each monitor. The pie chart in each panel shows the estimated size-resolved

16   mass distribution provided by the WRAS, with the same color codes used previously. The overall

17   size of the pie is proportional to the integrated mass over each event.

18   Figure 5 presents results for mineral and combustion sources. With the exception of the burn

19   periods of scented candles – for which all LCMs had little response – the LCMs generally reported

20   event-integrated concentrations within a factor of 2 of the estimated true $PM_{2.5}$ for all sources in

21   these categories. Relative responses of the LCMs were similar for the vacuum and Test Dust, for

22   the stick incense and mosquito coil sources, for the two humidifier experiments, and for the two

23   parts of the unscented candle source; but the patterns were different across these source groups.

24   Figure 6 presents the event-integrated $PM_{2.5}$ comparison for varied cooking activities. All the

25   LCMs missed the boiled potatoes and broiled bacon, potatoes, and Brussels sprouts. Ratios of

26   baseline subtracted integrations were also near zero for the toast; the as-measured values were

27   substantially higher if still small overall. The responses across LCMs varied the least for popcorn;

1   e-grilling of a beef burger; stir-frying spinach; and pan-frying eggs, bacon or fish. The highest

2   response factors and largest variations across LCMs occurred for oil heating. Pan-fried fish had a

3   different response pattern than pan-fried bacon and eggs, due to different particle size distribution.

4   Overall, the event-integrated analysis provides findings that are consistent with those of the

5   correlation analysis. All of the LCMs provided at least semi-quantitative responses (roughly within

6   a factor of 2) to most of the sources, but all missed small to medium sized sources comprised

7   entirely of particles smaller than about 0.25 μm optical diameter.

8   **3.4. Accuracy for quantifying event-integrated PM_{10}**

9   Figures 7–8 present the event-integrated PM_{10} and $PM_{2.5}$ concentrations for the low-cost

10   monitors that report both parameters and also presents the same results for the adjusted WRAS.

11   These results have several features that are relevant to the interpretation of PM_{10} reported by LCMs.

12   The first finding is that one of the three AVP units reported much higher PM_{10} than the other two

13   units in 13 of the 24 experiments. The AVP and the AQE commonly reported substantially higher

14   PM_{10} than $PM_{2.5}$ when the adjusted WRAS indicated similar concentrations for the two PM size

15   cuts. The AQE, AVP and PAI all reported varied, non-zero PM_{10} for the boiled potatoes, and

16   broiled Brussels sprouts, bacon and potatoes, even though these sources appeared to have almost

17   no coarse mode particles based on the adjusted WRAS. There were several sources for which an

18   LCM reported PM_{10} that was similar to the adjusted WRAS but much higher than the $PM_{2.5}$

19   reported by the LCM for the same source, even though the WRAS indicated no substantial coarse

20   mode mass; examples include the post-snuff phases of candles, toast, and e-grilled burner. Overall,

21   these results indicate that the PM_{10} data from the low-cost monitors may be less consistent and

22   reliable than the reported $PM_{2.5}$.

23   **4.   Discussion**

24   All of the LCMs tested in this study reported $PM_{2.5}$ within a factor of two of the estimated true

25   mass concentrations for most of the sources evaluated. This was an improvement on the

26   performance of home IAQ monitors as a group compared to our prior study[22]. The aerosols that

1   were effectively measured varied in size distribution and chemical composition; but all had at least

2   some mass in the optical sensing range of the research-grade WRAS monitor. There were some

3   sources for which the $PM_{2.5}$ reported by an LCM was higher than the *total* $PM_{2.5}$ mass estimated

4   from the adjusted WRAS even though much of the mass reported by the WRAS for that source

5   was contributed by particles smaller than the optical size detection range; this is another indicator

6   of the sensors in the LCMs over-weighting the smallest particles that they detect. In contrast, most

7   of the LCMs reported concentrations that were less than half of the estimated actual $PM_{2.5}$ emitted

8   from vacuuming and Test Dust, for which most of the $PM_{2.5}$ was in particles larger than 1 μm.

9   The LCMs missed the $PM_{2.5}$ emitted from the steady burning of candles and electric or gas

10 cooking that did not involve frying, stir-frying or heating of oil. While this shows that these devices

11 still have limitations, it is important to recognize that professional monitors that rely on optical

12 sensing have similar blind spots.

13   The variability of LCM response factors by source complicates their use for quantitative

14 assessment of indoor concentrations and exposures. Professional grade monitors have this same

15 limitation and require gravimetric sampling for environment or source-specific calibration factors.

16 LCMs may nevertheless provide effective event detection and accurate if imprecise estimates of

17 the benefits of instituting controls or interventions if the mix of sources (and thus response factors)

18 is similar before and after the intervention. Research is needed to assess that possibility.

19   Although three LCMs (AQE, LE2, and PAI) used Plantower sensors with the same nominal

20 performance specifications, the integrated $PM_{2.5}$ mass concentrations reported by these devices

21 differed substantially for some sources. The AQE and PAI reported moderately different (relative

22 deviation of >10%) integrated $PM_{2.5}$ for incense, mosquito coils, burning candles, pan-frying

23 bacon, and stir-frying spinach. The LE2 reported significantly lower integrated mass than the AQE

24 and PAI for the humidifier operating without filter, test dust, vacuum, and cooking involving

25 frying. It is not known if the differences resulted from a different measurement configuration

26 across versions of the Plantower sensor or an adjustment of the sensor signal by the LE2.

1   There was generally high consistency across the three units of each model tested in this study.

2   Among the 18 units tested, we identified only one with a faulty sensor that impacted results. This

3   was easily identified by co-locating multiple units of a single device or could also be detected by

4   comparison to other LCMs. This is a check that home users could do by comparing multiple

5   devices in the presence of sources. When the unit with the bad sensor was excluded, the relative

6   standard deviations for all LCMs across most events was less than 5%. The exceptions were the

7   events in which much or all of the $PM_{2.5}$ presented in particles <0.25 μm or >1 μm. The PAI units

8   had the highest standard deviations, exceeding 8% in the cooking activities.

9   We note as a limitation that this study did not evaluate the effect of temperature or humidity on

10   LCM performance. Product specifications provided by the sensor manufacturers indicate that the

11   effect of temperature is negligible in the range of 10-40 ℃, but high humidity is known to affect

12   aerosol optical sensing and could be relevant in some residential applications.

13   **5. Conclusions**

14   Six low-cost IAQ monitors were evaluated for their responsiveness and accuracy in measuring

15    $PM_{2.5}$ and PM_{10} generated by common residential sources. All of the LCMs had semi-quantitative

16   responses (within a factor of two) to most of the sources but all had very little or no response when

17   the generated aerosols were entirely or almost entirely below the optical threshold of roughly 0.25

18   μm. With the exception of one monitor with a faulty sensor – which was easily identified using

19   simple quality assurance data review - there was close agreement across three unit of each monitor

20   for all the sources with substantial PM in the visible range of the optical sensors.

21

22

Table 1. Descriptions of Low-Cost Monitors

Device; Cost[1]	Data[2]	Particle sensor(s) and specifications for $PM_{2.5}$	Website for product information. Calibration and quality assurance information provided by manufacturer
Air Quality Egg 2018 version (AQE); US$225	1 min	Two Plantower PMS5003 [3] Effective range: 0–500 μg/m^3 Max. range: ≥1000 μg/m^3 Max. consistency error: 0~100 μg/m^3: ±10 μg/m^3 100~500 μg/m^3: ±10%	https://airqualityegg.com/home *Device reports $PM_{2.5}$ and PM_{10} as averages of concentrations reported by the two sensors. Each device is checked for consistency with other devices before shipping by exposure to incense smoke in a small room.*
IQAir AirVisual Pro (AVP); US$269	10 sec	AirVisual AVPM25b Effective range: 0–1798 μg/m^3	https://www.airvisual.com/ *Sensors calibrated through automatic process in controlled chamber, using distinct aerosols for PM_1, $PM_{2.5}$, PM_{10} using Grimm 11-A as reference. Firmware onboard diagnostic detects faults and reports to company server; customers contacted.*
Awair 2nd Edition (AW2); US$199	10 sec	Honeywell HPMA115S0 Accuracy @25±5ºC: 0–100 μg/m^3: ±15 μg/m^3 100–1000 μg/m^3: ±15%	https://getawair.com/products/awair-2nd-edition. *Provides $PM_{2.5}$ and estimated PM_{10} (μg/m^3) direct from sensor. Each device is checked for consistency with other devices and a reference sensor before shipping. Sensor rated for 5-7 y of continuous use. No recalibration or cleaning needed if used in typical indoor environments (e.g. office, residential, school).*
Kaiterra Laser Egg 2 (LE2); US$169	1 min	Plantower PMS3003 Same specification as PMS5003	https://www.kaiterra.com/en/laser-egg/ *If device configured with location, Kaiterra adjusts sensor output based on local outdoor PM (details proprietary); otherwise uses proprietary default calibration. Monitors tested in batches with varied sources including wood smoke and cigarette smoke.*
PurpleAir Indoor (PAI); US$179	80 sec	Plantower PMS1003 Same specification as PMS5003	https://www.purpleair.com/sensors *Provides data direct from sensor: PM_1, $PM_{2.5}$ and PM_{10} in μg/m^3, number concentrations (#/0.1L) of particles larger than the following optical diameters: 0.3, 0.5, 1.0, 2.5, 5.0, 10 μm.*
Ikair (IKA); ~US$150	1 min	TGF PM D4 Range: 0-1000 μg/m^3; Accuracy: 0–100 μg/m^3: ±10 μg/m^3 100–1000 μg/m^3: ±10%	http://www.tgftech.com/ *Provides $PM_{2.5}$ (μg/m^3) direct from sensor.*

[1] In October 2018. [2] Highest time resolution available. [3] Plantower documentation describes the analytical method as follows: "…collect scattering light in certain angle [and] obtain the curve of scattering light change with time. [By microprocessor, calculate] equivalent particle diameter and the number of particles with different diameter per unit volume based on MIE theory. Product documentation also reports "endurance max error" after 720 hours of operation: as ±15 μg/m^3 for 0~100 μg/m^3 and ±15% for 100~500 μg/m^3.

Table 2. Summary description of source activities

Source	Day[1]	Start time	Description	Peak PM$_{2.5}$ [2] $\mu g\ m^{-3}$	Peak PN[3] >10 nm, cm^{-3}	Est. PM$_{2.5}$ density [4]
Humidifier 1	10	10:24	Ultrasonic humidifier, cleaning cartridge removed; operated ~30 min	79	1.8×10^4	2.16
Humidifier 2	10	13:00	Ultrasonic humidifier, cleaning cartridge removed; operated ~90 min	119	2.4×10^4	2.22
Microwave popcorn	11	14:00	90 g popcorn (Newman's Own), heated in microwave 90 s	81	2.1×10^4	1.32
Incense stick 1	11	13:12	2 incense sticks (Shanthimalai Red Nag Champa) burned ~15 min	202	7.3×10^4	1.16
Toast white bread	12	9:12	6 slices of white bread, medium-toasted in used, 2-slice toaster	57	1.3×10^5	0.67
E-grilled burger	12	12:12	4 beef burgers (113 g each), cooked for 10 min on electric burger grill	126	1.5×10^5	0.89
Mosquito coil 1	12	15:06	Mosquito coil (Patio & Deck) burned for 15 min	125	1.1×10^3	1.18
Boiled potatoes	13	8:06	937g potatoes, peeled and cut; boiled for 25 min on gas stove	36	7.2×10^4	0.88
Unscented candles	13	11:36	6 unscented candles, lit with butane lighter, burn 54 min	102	9.2×10^4	1.05
Snuff candles	13	12:36	Extinguished candles and traced decay	163	9.7×10^4	1.03
Scented candles	13	15:54	3 scented candles, 3 wicks each, lit with butane lighter, burn 53 min	27	4.0×10^4	1.21
Snuff candles	13	16:54	Extinguished candles and tracked decay	54	4.5×10^4	1.52
Broil Br. sprouts	14	7:54	454 g brussels sprouts, broiled in oven at 204 ℃ for 20min	72	2.3×10^5	0.63
Arizona test dust	14	11:36	Arizona Test Dust (0-3μm) manually puffed from plastic blower	134	1.2×10^3	2.37
Stir-fry spinach	14	14:06	360 g spinach + 15 g canola oil, stir-fried in steel wok on gas burner	276	8.3×10^4	1.35
Mosquito coil 2	14	17:00	Mosquito coil (Patio & Deck) burned for 15 min	131	4.4×10^4	1.17
Heat olive oil	17	8:00	15 g olive oil brought to bubble in steel wok on induction stove	99	4.8×10^4	0.88
Vacuum	17	11:36	Vacuum with HEPA filter removed, operated for 15 min	224	3.0×10^3	2.89
Pan-fry eggs	17	14:12	4 eggs, fully cooked with 15 g canola oil on gas stove	249	1.2×10^5	1.19
Pan-fry bacon	18	17:00	3 strips uncured apple smoked bacon, pan-fried on gas stove for 10 min	843	3.8×10^5	1.20
Pan-fry fish	18	7:48	320 g Tilapia fillets, pan-fried with 15 g butter on gas stove	84	1.1×10^5	0.91
Broil bacon	18	10:54	3 strips uncured apple smoked bacon, broiled at 218 ℃ for 14 min	110	3.6×10^5	0.63
Incense stick 2	18	13:30	Incense stick (Shanthimalai Red Nag Champa); burned for ~60 min	378	6.9×10^4	1.65
Broil potatoes	19	16:12	940 g peeled potatoes coated with 20 g olive oil; broiled at 218 ℃ 25 min	115	2.5×10^5	0.64

15   TEOM Data Collection and Processing
16   A Tapered Element Oscillating Microbalance with Filter Dynamic Measurement System Model
17   1405-DF (Thermo Fisher Scientific), henceforth TEOM, was used as a reference PM$_{2.5}$ monitor.
18   The TEOM is designed to provide hourly resolved data for ambient air monitoring, which is
19   developed from measurements that occur over shorter intervals. For 6 minutes the TEOM operates
20   in a Base measurement mode in which sample air is heated to 30ºC then pulled through a filter
21   affixed to an oscillating element. As particles are collected on the filter, the oscillation frequency
22   changes and the collected mass is calculated. During the next 6 minutes, the TEOM operates in a
23   Reference mode, in which sample air is cooled and passed through the filter on the oscillating
24   element. The filtering and cooling process is designed to remove both particle and semi-volatile
25   gases that can be collected on the filter and bias PM measurements. Any change in oscillation that
26   occurs during the Reference measurement is assumed to be caused by the loss of semi-volatile
27   gases that can bias the PM measurement. The concentration is the base measurement minus the
28   reference measurement. During and following events with significant volatile fractions the
29   reference measurement can be negative, due to the fact that this clean volatile particle free air is
30   driving off previously collected mass.

31   The TEOM was configured to report out the Base and Reference measurements every 6 minutes.
32   The Base measurements are only updated each 12 minutes (as the Reference measurements are
33   updated on the alternating 12 min cycle). This is highly resolved for outdoors but not fast or
34   resolved enough for indoor sources. Thus, in our processing of TEOM data, we first imputed Base
35   values for each time step that had a repeated value of the Base reading (when the device was in
36   Reference mode). We then subtracted the Reference measurement from the imputed Base value to
37   calculate an estimated PM$_{2.5}$ concentration for each 6-min time step. An example of this is
38   provided in Figure 1.
